#### **Abstract**

This paper discusses a novel application of mathematical programming techniques to a regression problem. While least squares regression techniques have been used for a long time, it is known that their robustness properties are not desirable. Specifically, the estimators are known to be too sensitive to data contamination. In this paper we examine regressions based on Least-sum of Absolute Deviations (LAD) and show that the robustness of the estimator can be improved significantly through a judicious choice of weights. The problem of finding optimum weights is formulated as a nonlinear mixed integer program, which is too difficult to solve exactly in general. We demonstrate that our problem is equivalent to one similar to the knapsack problem and then solve it for a special case. We then generalize this solution to general regression designs. Furthermore, we provide an efficient algorithm to solve the general non-linear, mixed integer programming problem when the number of predictors is small. We show the efficacy of the weighted LAD estimator using numerical examples.

**Keywords:** Algorithms; Breakdown point; Knapsack problem; Nonlinear mixed integer programming; Robust regression

## **1 Introduction**

Consider the well-known statistical linear regression problem. We have  $n$  observations on some "dependent" variable y and some number  $p \ge 1$  of "independent" variables  $x_1, \ldots, x_p$ , for each one of which we know  $n$  values as well. We denote

$$
\mathbf{y} = \begin{pmatrix} y_1 \\ \cdot \\ \cdot \\ y_n \end{pmatrix}, \ \mathbf{X} = \begin{pmatrix} x_1^1 & \cdots & x_p^1 \\ \cdot & & \cdot \\ \cdot & & \cdot \\ x_1^n & \cdots & x_p^n \end{pmatrix} = \begin{pmatrix} \mathbf{x}^1 \\ \cdot \\ \cdot \\ \cdot \\ \mathbf{x}^n \end{pmatrix} = (\mathbf{x}_1, \ldots, \mathbf{x}_p),
$$

where  $\mathbf{y} \in \mathbb{R}^n$  is a vector of n observations,  $\mathbf{x}_1, \ldots, \mathbf{x}_p$  are column vectors with n components, and  $\mathbf{x}^1, \ldots, \mathbf{x}^n$  are row vectors with p components corresponding to the columns and rows of the  $n \times p$  matrix **X**, respectively. To rule out pathologies we assume throughout that the rank  $r(\mathbf{X})$  of **X** is full, *i.e.*, that  $r(\mathbf{X}) = p$ . If the regression model includes an intercept term, as is typical,  $x_1$  is a column of ones, but this is not required.

The statistical linear regression model is

$$
y = X\beta + \varepsilon,\tag{1}
$$

where  $\boldsymbol{\beta}^T = (\beta_1, \ldots, \beta_p)$  is the vector of parameters of the linear model and  $\boldsymbol{\varepsilon}^T = (\varepsilon_1, \ldots, \varepsilon_n)$ is a vector of  $n$  random variables corresponding to the error terms in the asserted relationship. The superscript T denotes "transposition" of a vector or matrix throughout this work. In the statistical model, the dependent variable  $y$  is a random variable for which we obtain measurements or observations that contain some "noise" or measurement errors that are captured in the error terms *ε*.

Although (1) gives the statistical model underlying the regression problem, the numerical problem faced is slightly different. For this, we write

$$
y = X\beta + r \tag{2}
$$

where given some parameter vector  $\beta$ , the components  $r_i$  of the vector  $\mathbf{r}^T = (r_1, \ldots, r_n)$  are the *residuals* that result, given the observations **y**, a fixed design matrix **X**, and the chosen vector  $\beta \in \mathbb{R}^p$ . It is well-known that when the errors  $\varepsilon$  are normally (Gaussian) distributed,

the least squares parameter estimator (which minimizes the  $\ell_2$ -norm  $\|\mathbf{y}-\mathbf{X}\boldsymbol{\beta}\|_2 = \sum_{i=1}^n (y_i-\mathbf{X}_i)$  $\mathbf{x}^i\boldsymbol{\beta}$ <sup>2</sup> of the residuals) has many desirable properties, having the minimum variance among all linear unbiased estimators, and (being the maximum likelihood estimator) achieving the minimum possible variance for all consistent estimators as the sample size becomes infinite.

Many other regression estimators, in addition to least squares, have been proposed in the statistical literature. These techniques have been introduced to improve upon least squares in some way. Among these techniques are those that are robust with respect to outliers, as it is known that least squares regression estimates are affected by wild observations. There have been several measures developed within the statistical literature that quantify the robustness of a regression estimator. In this paper, we focus on the *breakdown point* (c.f. [12]) to be formally defined in Section 2.

One of the earliest proposals for estimating regression parameters was regression performed using the  $\ell_1$ -norm, also called Least-sum of Absolute Deviations (LAD). This regression problem can be solved using linear programming, hence its interest in the operations research community. LAD regression has become more useful with the advent of interior point methods for solving linear programs and with the increase in computer processing speed (Portnoy and Koenker [11]). Furthermore, it is known that LAD regression is more robust than least squares (c.f. [3]). As far back as the 1960s and 1970s, it was noticed that empirically, LAD outperformed least squares in the presence of fat tailed data (c.f. [13]). However, it is only more recently that the robustness properties of LAD regression have been theoretically determined. For regression problems where there may be outliers in the dependent variable, LAD regression is a good alternative to least squares, and we show that judicious choice of weights can improve its robustness properties. Furthermore, LAD can be utilized to demonstrate that least squares is accurate when indeed it is (if the LAD and least squares estimates are similar); this can be useful, since the least squares estimator is more efficient than LAD in the presence of Gaussian errors.

In this paper, we study a mathematical program (nonlinear mixed integer program) that can be used to improve the robustness of LAD regression. We demonstrate that the introduction of nonuniform weights can have a positive impact on the robustness properties

of LAD regression. We develop an algorithm for determining these weights and demonstrate the usefulness of our approach through several numerical examples. Specifically, we develop an algorithm for choosing weights that can significantly improve the robustness properties of LAD regression. In order to study the weighted LAD regression problem, we use and apply linear and mixed integer programming techniques. Our studies indicate that weighted LAD regression should be seriously considered as a regression technique in many regression and forecasting contexts.

The structure of the paper is as follows. In Section 2, we introduce the LAD regression problem, summarize some of the pertinent research on LAD regression and its robustness properties. We show (in Section 3) that the problem of incorporating nonuniform weights can be formulated as a nonlinear mixed integer program. In Section 4, we demonstrate that this problem is equivalent to a problem related to the knapsack problem. In Section 5, we discuss a special case of the weight determination problem for which an optimal solution can be obtained. Using the insights gained in Sections 3-5, we develop an algorithm (in Section 6) to solve the problem approximately, and demonstrate that the algorithm significantly improves the robustness of the estimators through several numerical examples in Section 7.

#### **2 LAD Regression and Breakdown**

In the case of LAD regression, the general numerical problem (2) takes as the (optimal) parameters  $\boldsymbol{\beta} \in \mathbb{R}^p$  those that minimize the  $\ell_1$ -norm  $\|\mathbf{y} - \mathbf{X}\boldsymbol{\beta}\|_1 = \sum_{i=1}^n |y_i - \mathbf{x}^i\boldsymbol{\beta}|$  of the residuals. It is well-known that this problem can be formulated as the linear programming (LP) problem

$$
\begin{aligned}\n\min \qquad & \mathbf{e}_n^T \mathbf{r}^+ + \mathbf{e}_n^T \mathbf{r}^- \\
\text{such that} \qquad & \mathbf{X}\boldsymbol{\beta} + \mathbf{r}^+ - \mathbf{r}^- = \mathbf{y} \\
&\quad \boldsymbol{\beta} \text{ free, } \mathbf{r}^+ \geq \mathbf{0}, \mathbf{r}^- \geq \mathbf{0},\n\end{aligned}
$$
\n(3)

where  $e_n$  is the vector with all n components equal to one. In (3) the residuals **r** of the general form (2) are simply replaced by a difference  $\mathbf{r}^+ - \mathbf{r}^-$  of nonnegative variables, *i.e.*, we require that  $\mathbf{r}^+ \geq \mathbf{0}$  and  $\mathbf{r}^- \geq \mathbf{0}$ , whereas the parameters  $\boldsymbol{\beta} \in \mathbb{R}^p$  are "free"

to assume positive, zero, or negative values. From the properties of linear programming solution procedures, it follows that for any solution inspected by the simplex algorithm, either  $r_i^+ > 0$  or  $r_i^- > 0$ , but not both, thus giving  $|r_i|$  in the objective function depending on whether  $r_i > 0$  or  $r_i < 0$  for any  $i \in N$  where  $N = \{1, ..., n\}$ . Every optimal extreme point solution  $\beta^* \in \mathbb{R}^p$  of the LAD regression problem has the property that there exists a nonsingular  $p \times p$  submatrix  $\mathbf{X}_B$  of **X** such that

$$
\boldsymbol{\beta}^* = \mathbf{X}_B^{-1} \mathbf{y}^B, \ \mathbf{r}^+ = \max\left\{\mathbf{0}, \mathbf{y} - \mathbf{X}\boldsymbol{\beta}^*\right\}, \ \mathbf{r}^- = -\min\left\{\mathbf{0}, \mathbf{y} - \mathbf{X}\boldsymbol{\beta}^*\right\}
$$

where  $|B| = p$  and  $\mathbf{y}^B$  is the subvector of **y** corresponding to the rows of  $\mathbf{X}_B$  ( c.f. [3]).

The notion of the *breakdown point* of a regression estimator (due to Hampel [6]) can be found in [12] and is as follows. Suppose we estimate the regression parameters *β* by some technique  $\tau$  from some data  $(\mathbf{X}, \mathbf{y})$ , yielding the estimate  $\beta^{\tau}$ . If we contaminate m  $(1 \leq m < n)$  rows of the data in a way so that row i is replaced by some arbitrary data  $(\widetilde{\mathbf{x}}^i, \widetilde{y}_i)$ , we obtain some new data  $(\widetilde{\mathbf{X}}, \widetilde{\mathbf{y}})$ ). The same technique  $\tau$  applied to  $(\tilde{\mathbf{X}}, \tilde{\mathbf{y}})$  $\overline{ }$ yields estimates *β*<sup>τ</sup>  $\mathbf{X}, \widetilde{\mathbf{y}}$ that are different from the original ones. We can use any norm  $\|\cdot\|$  on  $\mathbb{R}^p$  to measure the distance  $\left\|\boldsymbol{\beta}^{\tau}\right\|$  $\mathbf{X}, \widetilde{\mathbf{y}}$  $\left\| -\beta^{\tau} \right\|$  of the respective estimates. If we vary over *all* possible choices of contamination then this distance either stays bounded or not. Let

$$
b(m, \tau, \mathbf{X}, \mathbf{y}) = \sup_{\widetilde{\mathbf{X}}, \widetilde{\mathbf{y}}} \left\| \boldsymbol{\beta}^{\tau} \left( \widetilde{\mathbf{X}}, \widetilde{\mathbf{y}} \right) - \boldsymbol{\beta}^{\tau} \right\|
$$

be the maximum bias that results when we replace at most m of the original data  $(\mathbf{x}^i, y_i)$ by arbitrary new ones. The breakdown point of  $\tau$  is

$$
\alpha(\tau, \mathbf{X}, \mathbf{y}) = \min_{1 \leq m < n} \left\{ \frac{m}{n} : b(m, \tau, \mathbf{X}, \mathbf{y}) \text{ is infinite} \right\},
$$

*i.e.*, we are looking for the minimum number of rows of  $(X, y)$  that if replaced by arbitrary new data make the regression technique  $\tau$  break down. We divide this by n to get  $\frac{1}{n} \leq$  $\alpha(\tau, \mathbf{X}, \mathbf{y}) \leq 1$ . In practice,  $\alpha(\tau, \mathbf{X}, \mathbf{y}) \leq .5$ , since otherwise it is impossible to distinguish between the uncontaminated data and the contaminated data. The breakdown point of LAD as well as least squares regression is  $\frac{1}{n}$  or asymptotically 0, see *e.g.*, [12]. Clearly, the larger the breakdown point, the more robust is the regression estimator.

However, LAD regression is more robust than least squares in the following manner. The finite sample breakdown point of the LAD regression estimator is the breakdown point of LAD regression with a fixed design matrix **X** and contamination restricted only to the dependent variable **y**, denoted by  $\alpha(\tau, \mathbf{y}|\mathbf{X})$ . The finite sample breakdown point, or conditional breakdown point, was introduced by Donoho and Huber ([1]). The finite sample breakdown point has been studied by many authors; see, *e.g.*, [2], [7], [4], and [8]. Ellis and Morgenthaler ([2]) appear to be the first to mention that the introduction of weights can improve the finite sample breakdown point of LAD regression, but they only show this for very small data sets. Mizera and Müller  $([9])$  examine this question in more detail, showing that the predictors **X** can be chosen to increase the breakdown point of LAD.

In this paper, we use the notation and framework set forth by Giloni and Padberg ([4]). Let  $N = \{1, \ldots, n\}$  and let  $U, L, Z$  be a mutually exclusive three-way partition of N such that  $|U \cup L| = q$ . Let **e** be a column vector of ones and let **X**<sub>Z</sub> be the submatrix of **X** whose row indexes are in Z. Similarly, we define  $X_U$  and  $X_L$ . The subscripts of U and L on **e** denote a vector of ones of appropriate dimension. Giloni and Padberg ([4]) define the notion of q-stability of a design matrix as follows. **X** is  $q$ -stable if  $q \geq 0$  is the largest integer such that

$$
\mathbf{X}_Z \boldsymbol{\xi} + \boldsymbol{\eta}^+ - \boldsymbol{\eta}^- = \mathbf{0}, \ (-\mathbf{e}_U^T \mathbf{X}_U + \mathbf{e}_L^T \mathbf{X}_L) \boldsymbol{\xi} + \mathbf{e}_Z^T (\boldsymbol{\eta}^+ + \boldsymbol{\eta}^-) \le 0 \tag{4}
$$

$$
\boldsymbol{\xi} \neq \boldsymbol{0}, \qquad \boldsymbol{\eta}^+ \geq \boldsymbol{0}, \qquad \boldsymbol{\eta}^- \geq \boldsymbol{0} \tag{5}
$$

is not solvable for any  $U, L, Z$ . They prove that a design matrix **X** is q-stable if and only if  $\alpha(\ell_1, \mathbf{y}|\mathbf{X}) = \frac{q+1}{n}$ . This is in direct contrast to least squares regression where its finite sample breakdown point is  $\frac{1}{n}$  or asymptotically 0. They show that the finite sample breakdown point of LAD regression can be calculated by the following mixed integer program MIP1 (where  $M > 0$  is a sufficiently large constant and  $\varepsilon > 0$  is a sufficiently small constant):

$$
MIP1 \quad \min \sum_{i=1}^{n} u_i + \ell_i = q + 1
$$
  
such that 
$$
\mathbf{x}^i \xi + \eta_i^+ - \eta_i^- + s_i - t_i = 0 \quad \text{for } i = 1, ..., n
$$

$$
s_i - Mu_i \le 0, \quad t_i - M\ell_i \le 0 \quad \text{for } i = 1, ..., n
$$

$$
\eta_i^+ + \eta_i^- + Mu_i + M\ell_i \le M \quad \text{for } i = 1, ..., n
$$

$$
u_i + \ell_i \le 1 \quad \text{for } i = 1, ..., n
$$

$$
\sum_{i=1}^{n} \eta_i^+ + \eta_i^- - s_i - t_i \le 0,
$$

$$
\sum_{i=1}^{n} s_i + t_i \ge \varepsilon
$$

$$
\xi \text{ free}, \eta^+ \ge 0, \eta^- \ge 0, \mathbf{s} \ge 0, \mathbf{t} \ge 0, \quad u_i, \ell_i \in \{0, 1\} \text{ for } i = 1, ..., n.
$$

In our case, we are interested in weighted LAD regression. The weighted LAD regression problem also can be formulated as a linear program, as follows.

$$
\min \sum_{i=1}^{n} w_i (r_i^+ + r_i^-)
$$
\nsuch that

\n
$$
\mathbf{X}\boldsymbol{\beta} + \mathbf{r}^+ - \mathbf{r}^- = \mathbf{y}
$$
\n
$$
\boldsymbol{\beta} \text{ free, } \mathbf{r}^+ \geq \mathbf{0}, \mathbf{r}^- \geq \mathbf{0}.
$$
\n(6)

Here, we assume that the residual associated with observation  $i$  is multiplied by some weight,  $w_i$ , where we assume that  $0 < w_i \leq 1$  without restriction of generality. We note that if we were to set  $w_i = 0$ , we would essentially "remove" observation i from the data. We do not permit this, although, if some (optimal) weight is sufficiently near 0, the user can choose to remove the observation from the data set.

We now note that since  $(r_i^+ - r_i^-) = (y_i - \mathbf{x}^i)\theta$ , and by the simplex method either  $r_i^+ > 0$  or  $r_i^- > 0$  but not both, then  $|w_i(r_i^+ - r_i^-)| = w_i(r_i^+ + r_i^-)$ . Therefore, if we were to transform our data by setting  $(\hat{\mathbf{x}}^i, \hat{y}_i) = w_i (\mathbf{x}^i, y_i)$ , then  $(\hat{y}_i - \hat{\mathbf{x}}^i \boldsymbol{\beta}) = w_i (r_i^+ - r_i^-)$ . In such a case, the linear program (6) can be reformulated as

$$
\begin{aligned}\n\min \qquad & \mathbf{e}_n^T \mathbf{r}^+ + \mathbf{e}_n^T \mathbf{r}^- \\
\text{such that} \qquad & w_i \mathbf{x}^i \boldsymbol{\beta} + \mathbf{r}^+ - \mathbf{r}^- = w_i y_i \quad \text{for } i = 1, \dots, n \\
&\qquad \boldsymbol{\beta} \text{ free, } \mathbf{r}^+ \geq \mathbf{0}, \mathbf{r}^- \geq \mathbf{0}.\n\end{aligned}
$$

This shows that weighted LAD regression can be treated as LAD regression with suitably transformed data. Therefore, the problem of determining the breakdown of weighted LAD regression with known weights corresponds to determining the breakdown of LAD regression with data  $(\mathbf{X}, \hat{\mathbf{y}})$ .

The equivalence of weighted LAD regression and ordinary LAD regression on transformed data is also useful in other contexts. For example, LAD regression can be adapted to the nonparametric estimation of smooth regression curves (see [14] for a general discussion of nonparametric regression estimation), by local fitting of weighted LAD regressions  $([15]; [16])$ . Formulations of the type in this section allowed Giloni and Simonoff  $([5])$  to derive the exact breakdown properties of local LAD regression at any evaluation point, and to make recommendations concerning the best choice of weight function.

In the next section, we formulate the problem of determining the set of weights that maximizes the breakdown point of weighted LAD regression.

#### **3 Problem Formulation**

The task of determining the weights that maximize the finite sample breakdown point of LAD regression is a complicated one. If one were to try to solve this problem by brute force, it would require the inspection of all or a large subset of all vectors (if this is possible) **w**  $\in \mathbb{R}^n$ , the transformation of the data described above  $(\hat{\mathbf{x}}^i, \hat{y}_i) = w_i(\mathbf{x}^i, y_i)$ , and then the solution of MIP1 for each case. Instead, we formulate this problem as a nonlinear mixed integer program. For the solution methods we discuss below, we make the standard assumption that the design matrix **X** is in general position, *i.e.*, every  $p \times p$  submatrix of **X** has full rank. We do this in order to simplify the analysis that follows. However, we note that even in the case where this assumption is violated, the methodology that we develop is still valid. This is quite different from many so-called high breakdown regression techniques (ones where the breakdown point can be as high as .5), where the value of the breakdown point of the estimators depends upon whether or not the design matrix is in general position; see [12], p. 118. The mixed integer program is

NLMIP 
$$
\max_{\mathbf{w}} \min \sum_{i=1}^{n} (u_i + \ell_i)
$$
  
such that 
$$
w_i \mathbf{x}^i \boldsymbol{\xi} + \eta_i^+ - \eta_i^- + s_i - t_i = 0 \text{ for } i = 1, ..., n
$$
 (7)

such that

$$
s_i - Mu_i \le 0, \quad t_i - M\ell_i \le 0 \quad \text{for } i = 1, \dots, n
$$
\n
$$
(8)
$$

$$
\eta_i^+ + \eta_i^- + Mu_i + M\ell_i \le M \quad \text{for } i = 1, \dots, n
$$
\n
$$
(9)
$$

$$
u_i + \ell_i \le 1 \quad \text{for } i = 1, \dots, n \tag{10}
$$

$$
\sum_{i=1}^{n} \eta_i^+ + \eta_i^- - s_i - t_i \le 0 \tag{11}
$$

$$
\sum_{i=1}^{n} s_i + t_i \ge \varepsilon \tag{12}
$$

$$
w_i \le 1 \quad \text{for } i = 1, \dots, n \tag{13}
$$

$$
\boldsymbol{\xi} \text{ free}, \boldsymbol{\eta}^+ \geq \mathbf{0}, \, \boldsymbol{\eta}^- \geq \mathbf{0}, \mathbf{s} \geq \mathbf{0}, \mathbf{t} \geq \mathbf{0}, \, u_i, \ell_i \in \{0, 1\} \text{ for } i = 1, \dots, n. \text{ (14)}
$$

Note that  $\xi_j$  is unrestricted for  $j = 1, \ldots, p$ . Also note that  $NLMIP$  is a nonlinear problem because of the first term in the left hand side of (7). Since nonlinear mixed integer programs are extremely difficult to solve we will resort to heuristics for finding good feasible solutions. In order to do so, we note that if the weights  $\mathbf{w} \in \mathbb{R}^n$  are fixed, then NLMIP is just MIP1 with transformed data. Therefore, if we were to focus on only a specific sets of weights, we could determine which set is the best by solving the different MIPs and choosing the set that had the largest objective function value among the MIPs considered. However, as mentioned by Giloni and Padberg  $([4])$ , MIP1 can take a long time to solve for large data sets. We thus provide an alternative way of solving  $MIP1$  that is quite efficient when p is small. We note that this alternative way is similar to the proposal of Mizera and Müller ([9]). We provide its statement and proof here, as we feel it is useful in understanding our framework for selecting weights.

**Proposition 1** *In order to determine the finite sample breakdown point of LAD regression,*

*it is sufficient to consider*  $\binom{n}{p-1}$  *candidate solutions for the vector*  $\xi \in \mathbb{R}^p$  *in (4) and (5)*.

*Proof.* Consider a three-way partition  $U_1$ ,  $L_1$ ,  $Z_1$  of N where  $U_1 \cap L_1 = \emptyset$ ,  $Z_1 = N - U_1 - L_1$ , and  $q = |U_1 \cup L_1|$ . Note that (4) has no solution if and only if the objective function value of the following optimization problem is strictly greater than zero.

$$
OF = min \t -\sum_{i \in U_1} \mathbf{x}^i \boldsymbol{\xi} + \sum_{i \in L_1} \mathbf{x}^i \boldsymbol{\xi} + \sum_{i \in Z_1} \eta_i^+ + \eta_i^-
$$
  
such that  $\mathbf{X}_{Z_1} \boldsymbol{\xi} + \boldsymbol{\eta}^+ - \boldsymbol{\eta}^- = \mathbf{0}$   $(15)$   
 $\boldsymbol{\xi} \neq \mathbf{0}, \quad \boldsymbol{\eta}^+ \geq \mathbf{0}, \boldsymbol{\eta}^- \geq \mathbf{0}$ 

We note that since this problem includes a constraint of the form  $\xi \neq 0$ , its study as a linear program is more difficult. Therefore, we argue as follows. If we were to assume that there exist  $\xi_0 \in \mathbb{R}^p$ ,  $\xi_0 \neq \mathbf{0}$ , such that  $OF < 0$ , then consider  $\xi = \psi \xi_0$  where  $\psi > 0$ is some constant. If  $i \in U_1 \cup L_1$ , then the sign of  $x^i \xi$  is the same as that of  $x^i \xi_0$ . If  $i \in Z_1$ ,  $\eta_i^+ + \eta_i^- \ge |\mathbf{x}^i \xi|$  because of (15), and since we are minimizing, equality will hold. Therefore,  $\xi = \psi \xi_0$  results in OF being multiplied by  $\psi$ . It follows that  $OF < 0$  (actually  $OF \to -\infty$  since we could let  $\psi \to \infty$ ). It can be shown similarly if  $OF = 0$  or  $OF > 0$  that  $\xi = \psi \xi_0$  does not change the sign of *OF*. Therefore we set  $\xi_j = \gamma$  where  $\gamma > 0$  and without restriction of generality we let  $j = 1$ . This changes the optimization to the following linear program:

$$
OF1 = min \t -\sum_{i \in U_1} \mathbf{x}^i \boldsymbol{\xi} + \sum_{i \in L_1} \mathbf{x}^i \boldsymbol{\xi} + \sum_{i \in Z_1} \eta_i^+ + \eta_i^-
$$
  
such that  $\mathbf{X}_Z \boldsymbol{\xi} + \boldsymbol{\eta}^+ - \boldsymbol{\eta}^- = \mathbf{0}$   
 $\xi_1 = \gamma$   
 $\boldsymbol{\xi}$  free,  $\boldsymbol{\eta}^+ \geq \mathbf{0}, \boldsymbol{\eta}^- \geq \mathbf{0}$ 

All basic feasible solutions to this linear program are of the form  $\boldsymbol{\xi} = \begin{pmatrix} 1 & 0 \\ 0 & \mathbf{0} \end{pmatrix}$  $\mathbf{X}_B$  $\bigwedge^{-1}$  (  $\gamma$ **0**  $\overline{ }$ where  $\mathbf{X}_B$  is a  $(p-1) \times (p)$  submatrix of  $\mathbf{X}_Z$  with rank  $p-1$  and we assume that the  $\begin{pmatrix} 1 & 0 \ \mathbf{X}_B \end{pmatrix}$  $\sqrt{ }$ of order p is of full rank. (Note that if a row of **X** is of the form (1 **0**) then this would only reduce the number of possible basic feasible solutions.) By the

fundamental theorem of linear programming (c.f. [10], Theorem 1), a solution with  $OF1 \leq 0$ exists if and only if a basic feasible solution exists with  $OF1 \leq 0$ . Thus if  $OF1 \leq 0$  then  $OF \leq 0$ . We note that if an optimal solution to  $OF$  had  $\xi_1 = \gamma < 0$  then it is possible that  $OF \leq 0$  when  $OF1 > 0$  since  $\gamma > 0$  in the linear program. However, this is no concern to us since we need to consider all possible three-way partitions and we point out that switching the roles of  $U_1$  and  $L_1$  effectively changes the sign of  $\xi_1$ . Since there are at most n possible rows of **X** that could be included in  $\mathbf{X}_{Z_1}$  there are no more than  $\binom{n}{p-1}$  possible subsets of **X**<sup>Z</sup> for any Z. Therefore, the proposition follows.  $\Box$ 

## **4 An equivalent problem**

In this section, we show that the problem  $NLMIP$  can be reduced to a problem which is related to the knapsack problem. Consider the following problem:

$$
EQMIP \qquad \max_{\mathbf{w}} \ \min_{\mathbf{z}, \boldsymbol{\xi}} \sum_{i=1}^{n} z_i \tag{16}
$$

such that 
$$
\sum_{i=1}^{n} |w_i \mathbf{x}^i \boldsymbol{\xi} | z_i \ge 0.5 \sum_{i=1}^{n} |w_i \mathbf{x}^i \boldsymbol{\xi}|
$$
 (17)

$$
w_i \le 1 \quad \text{for } i = 1, \dots, n \tag{18}
$$

$$
\xi \neq 0, \quad z_i \in \{0, 1\} \text{ for } i = 1, \dots, n. \tag{19}
$$

Imagine a hiker who has available n objects that he can choose from and the weight of the ith object is  $|\alpha_i|$ , where  $\alpha_i = w_i \mathbf{x}^i \boldsymbol{\xi}$ . The hiker has to select a subset of these objects such that the weight of the subset is at least half of the weight of the entire set. Obviously, the problem is trivial if the weights  $|\alpha_i|$  were known. One would order the objects by nondecreasing weights and then select them one by one until the total weight of the selected items is greater than or equal to half of the total weight of all of the  $n$  objects. The problem is made difficult by the fact that the weights  $|\alpha_i|$  are determined by several unknown variables (*ξ* and *w*), and further complications arise due to the *max-min* nature of the objective function. Nevertheless, this demonstration of equivalence and the insight that we gain from understanding the problem in this manner plays an important role in the development of the algorithm to follow. In the following proposition, we show that the two problems are equivalent in the sense that there is a simple method of constructing the optimal solution of one when the optimal solution of the other is known.

#### **Proposition 2** *The problems* NLM IP *and* EQM IP *are equivalent.*

*Proof.* Let us assume that the optimal solution of  $EQMIP$  is known. Let  $\mathcal Z$  denote the subset of indices from the set  $\{1,\ldots,n\}$  for which  $z_i = 1$ . We now construct a solution for  $NLMIP$  from the solution of  $EQMIP$  as follows:

If 
$$
i \notin \mathcal{Z}
$$
 and  $\alpha_i < 0$ , then set  $\eta_i^+ = -\alpha_i$ , 
$$
(20)
$$

$$
\text{if } i \notin \mathcal{Z} \text{ and } \alpha_i \ge 0, \text{ then set } \eta_i^- = \alpha_i,\tag{21}
$$

$$
\text{if } i \in \mathcal{Z} \text{ and } \alpha_i < 0, \text{ then set } s_i = -\alpha_i \text{ and } u_i = 1 \text{ and} \tag{22}
$$

$$
\text{if } i \in \mathcal{Z} \text{ and } \alpha_i \ge 0, \text{ then set } t_i = \alpha_i \text{ and } \ell_i = 1. \tag{23}
$$

Set all other variables in  $NLMIP$  to zero. Let us denote the set of indices i satisfying (20)-(23) by  $\mathcal{G}_1, \mathcal{G}_2, \mathcal{G}_3$  and  $\mathcal{G}_4$  respectively. Note that  $\mathcal{G}_3 \cup \mathcal{G}_4 = \mathcal{Z}$  and  $\mathcal{G}_1 \cup \mathcal{G}_2 = \mathcal{Z}^c$ . Let  $\alpha = \sum_{i=1}^n |\alpha_i|$ . Let  $M = max_{i \in \mathcal{Z}} |\alpha_i|$  and let  $\varepsilon = \sum_{i \in \mathcal{Z}} |\alpha_i|$ . We first show that  $\varepsilon > 0$ . If we assume the contrary, *i.e.*,  $\varepsilon = 0$ , then it implies that the left hand side of (17) is zero and consequently, so is the right hand side of (17) and the optimal value of the objective function is 0. This means that for each i, either  $w_i = 0$  or  $\mathbf{x}^i \boldsymbol{\xi} = 0$ . Note that the assumptions that **X** is in general position and  $\xi \neq 0$ , implies that at least one of the  $\mathbf{x}^i \xi \neq 0$ . Then for that i, we can choose  $w_i = 1$  and  $z_i = 1$  and show that the optimum value of the objective can be increased to 1, which in turn implies that the solution could not be optimal. We now show that the solution constructed for  $NLMIP$  is feasible. It is fairly obvious from the construction of the solution that the constraints  $(7)-(14)$  are satisfied, except the inequality in (11). To show that this holds, we note that

$$
\sum_{i=1}^{n} (\eta_i^+ + \eta_i^- - s_i - t_i) = \sum_{i \in \mathcal{G}_1} \eta_i^+ + \sum_{i \in \mathcal{G}_2} \eta_i^- - \sum_{i \in \mathcal{G}_3} s_i - \sum_{i \in \mathcal{G}_4} t_i
$$
(24)

$$
= \sum_{i \notin \mathcal{Z}} |\alpha_i| - \sum_{i \in \mathcal{Z}} |\alpha_i| \text{ (from (20 - 23))}
$$
 (25)

$$
= \sum_{i=1}^{n} |\alpha_i| - 2 \sum_{i \in \mathcal{Z}} |\alpha_i| \tag{26}
$$

$$
\leq 0 \text{ (from (17))}.
$$

So far we have shown that the optimal solution for  $EQMIP$  is feasible for  $NLMIP$ . To show that this solution is also optimal for NLM IP, we assume the contrary, *i.e.*, assume that there is a solution to  $NLMIP$  which has a higher value of the objective function than the optimal solution to  $EQMIP$ . From this supposed solution of  $NLMIP$ , we construct a new solution for  $EQMIP$  by setting  $z_i = u_i + \ell_i$ . It is easy to verify that the new solution is feasible for  $EQMIP$ , by observing the following: (a) An optimal solution to  $NLMIP$  has an equivalent solution, which is also optimal, in which at most one of the four variables  $\eta_i^+$ ,  $\eta_i^-, s_i$  and  $t_i$  for any i can be positive. (b) When  $\eta_i^+$  or  $\eta_i^-$  is positive, the corresponding  $u_i = \ell_i = 0$ . (c) When  $s_i$  (or  $t_i$ ) is positive, then  $u_i = 1$  (or  $\ell_i = 1$ ). (d) Using (a), (b) and (c), one reverses the arguments in  $(24)-(27)$  to show that the solution of  $EQMIP$  so obtained satisfies the constraint (17). With this construction, it is now easy to see that this solution has an optimal value of the objective function that is higher than that of the assumed optimal solution of  $EQMIP$ . This contradiction shows that the optimal solution of EQMIP must also be an optimal solution of the NLMIP.

To finish the proof, one must now show that a solution of NLMIP has an equivalent solution which is also an optimal solution of  $EQMIP$ . The construction of this is done by setting  $z_i = u_i + \ell_i$ , and the proof of optimality can be obtained by reversing the arguments given above.  $\Box$ 

#### **5 The case of uniform design simple linear regression**

In this section, we discuss the special case of simple linear regression  $(p = 2)$  with a uniform design, i.e.,  $x_1^i = 1$  and  $x_2^i = i$ , for  $i = 1, ..., n$  (there is no loss of generality in taking the values of  $x_2^i$  as the integers; any equispaced set of values yields the same weights). We refer to this problem as the *uniform simple linear* problem. We show how to obtain an exact solution for this problem. The problem stated in  $(16)-(19)$  without any restriction on  $w_i$ now becomes:

$$
USLMIP \qquad \max_{\mathbf{w}} \ \min_{\mathbf{z}, \boldsymbol{\xi}} \sum_{i=1}^{n} z_i \tag{28}
$$

such that 
$$
\sum_{i=1}^{n} |w_i(\xi_1 + i\xi_2)| z_i \ge 0.5 \sum_{i=1}^{n} |w_i(\xi_1 + i\xi_2)|
$$
 (29)

$$
\xi \neq 0, \quad z_i \in \{0, 1\} \text{ for } i = 1, ..., n.
$$
 (30)

A crucial result for determining the optimal values of  $w_i$  and  $\xi$  is given by the following lemma.

**Lemma 1** For the problem USLMIP, there is an optimum solution of  $w_i$ , which is sym*metrical, i.e.,*  $w_i = w_{n-i}$  *for*  $i = 1, \ldots, n$ *.* 

*Proof.* Define  $\phi_i = \xi_1 + i\xi_2$  and let the optimal values of  $\xi_1 = \delta_1$  and  $\xi_2 = \delta_2$ ; this implies that  $\phi_i = \delta_1 + i\delta_2$ . Construct a new solution by selecting  $\xi_1 = \delta_1 + n\delta_2$  and  $\xi_2 = -\delta_2$ . We refer to the function  $\phi$  for the new solution as  $\bar{\phi}$  to distinguish it from the original solution. Then  $\bar{\phi}_i = \delta_1 + (n-i)\delta_2$ , or  $\phi_i = \bar{\phi}_{n-i}$ . Note that as far as the regression problem is concerned, it is as if the two solutions differ only in the arrangements of the entries of the **x**ξ vector. This means that there is an optimal solution for which  $w_i = w_{n-i}$  since a symmetric choice of  $w_i$  will cater to both choices of  $\phi$  and  $\phi$ .  $\Box$ 

Based on the above result, we limit ourselves to symmetric linear functions for  $w_i$ . More explicitly, the functions we choose to examine are linear functions of the distance from the center of the range of **x**, being of the form:

$$
w_i = \begin{cases} w^0 + iw^1 \text{ if } i \leq n/2 \\ w^0 + (n-i)w^1 \text{ if } i > n/2. \end{cases}
$$

We note that the problem defined in (28)-(30) is invariant in scaling for **w** and *ξ*. Therefore, without loss of generality, we can impose two conditions such as  $w^0 = \xi_1 = 1$ . Thus the simple linear problem reduces to the problem of finding just two parameters  $w<sup>1</sup>$  and  $\xi_2$ . Clearly, the two unknown quantities also depend on the value of  $n$ , the size of the problem. To remove this dependency, we convert the problem in (28)-(30) to an equivalent continuous problem in which the variable i is replaced with a variable x, where  $0 \leq x \leq 1$ . After solving this problem by conducting a search over the two unknown parameters, we re-convert the solution to the discrete case. The solutions obtained are  $w^1 = 4/n$  and  $\xi_2 = -1.35/n$ . The optimal value of the objective function in the continuous version of the problem is 0.3005n. This shows that the finite sample breakdown point of weighted LAD regression can reach over 30%. Note that if we simplified the problem by not considering the weights **w** (*i.e.*,  $w_i = 1$  for  $i = 1, \ldots, n$ , then the optimum breakdown for the continuous version of this problem is  $0.25n$  (c.f. [2]). This implies that for the uniform simple linear problem, the breakdown can be increased by about 20% by a judicious choice of weights.

The solution to the uniform simple linear problem after normalizing the weights such that  $w_i \leq 1$  for  $i = 1, \ldots, n$  is

$$
w_i = \begin{cases} \frac{1+i\left(\frac{4}{n}\right)}{1+\left\lfloor\frac{n}{2}\right\rfloor\left(\frac{4}{n}\right)} & \text{if } i \leq n/2\\ \frac{1+(n-i)\left(\frac{4}{n}\right)}{1+\left\lfloor\frac{n}{2}\right\rfloor\left(\frac{4}{n}\right)} & \text{if } i > n/2. \end{cases}
$$

Thus the selected weights range from approximately  $\frac{1}{3}$  to 1. Our algorithm for the determination of general weights given in the next section is based upon this solution for the uniform simple linear problem.

## **6 Weights for General Regression Designs**

In this section, we describe a general weight-determination algorithm, and describe in more detail how NLMIP can be solved once the weights are chosen. The key idea in generalizing the weights is to note that the symmetric linear weights have the property that the weights decrease linearly with the distance from the "center" of the range of the predictor. The proposed general weights have a corresponding property, decreasing linearly with the sum of the distances for the predictors from the coordinatewise median of the observation, where the distances are scaled by the range of each predictor. The median is chosen as the center of the data since the LAD estimator for univariate location is the median. This yields the following algorithm for choosing the weights.

#### **Algorithm for choosing weights**

**Step 1:** Let  $z_j^i = (x_j^i - \min_i\{x_j^i\})/\max_i\{x_j^i\}, j = 1, \ldots, p$  (if  $\mathbf{x}_1$  is a column of ones, set  $z_1^i = 0$  for all i). For  $j = 1, \ldots, p$ , let  $m_j$  denote the median of the entries  $z_j^i$  for  $i = 1, \ldots, n$ . **Step 2:** Let  $r_i = \sum_{j=1}^p |z_j^i - m_j|$ . **Step 3:** Let  $r_i = (r_i - \min_{\nu} r_{\nu})/(\max_{\nu} r_{\nu} - \min_{\nu} r_{\nu}).$ **Step 4:** Let  $w_i = 1 - \frac{2}{3}r_i$ .

Note that steps 3 and 4 of the algorithm guarantee that these weights are (virtually) identical to those derived earlier for the uniform simple linear case when the data take that form.

Once the weights are chosen, the results of section 3 provide a way of approximately solving  $EQMIP$ , and hence  $NLMIP$ . The details are as follows.

#### **Algorithm for solving** EQMIP

**Step 1:** Let N denote the set  $\{1, \dots, n\}$ . Let  $\mathcal{K}_k$  denote all of the subsets of N, such that  $|K_k| = p - 1$  for  $k = 1, \dots, r$ . Clearly,  $r = n!/((p - 1)!(n - p + 1)!)$ . For  $k = 1, \dots, r$ , solve the following system of linear equations for the unknown  $p \times 1$  vector  $\xi^k$ :

$$
w_i \mathbf{x}^i \boldsymbol{\xi}^k = 0 \quad \text{for} \quad i \in \mathcal{K}_k
$$

and  $\xi_1^k = 1$ . Note that this system is guaranteed to have a unique solution, based on the assumptions on **x**<sup>i</sup> . Let

$$
\alpha_i^k = w_i \mathbf{x}^i \boldsymbol{\xi}^k.
$$

**Step 2:** Reorder the elements  $|\alpha_i^k|$  for  $i = 1, ..., n$  in decreasing order so that  $|\alpha_i^k|$  now

denotes the *i*th order statistic. Identify the smallest index  $m^*(k)$  satisfying

$$
\sum_{i=1}^{m^*(k)} |\alpha_i^k| \ge 0.5 \sum_{i=1}^n |\alpha_i^k|.
$$

**Step 3:** Find  $m^* = \min_k m^*(k)$ . Let  $k^*$  be the value of k for which this is minimum. The solution is given by:

If 
$$
i > m^*
$$
 and  $\alpha_i^{k^*} < 0$ , then set  $\eta_i^+ = -\alpha_i^{k^*}$ ,  
if  $i > m^*$  and  $\alpha_i^{k^*} \ge 0$ , then set  $\eta_i^- = \alpha_i^{k^*}$   
if  $i \le m^*$  and  $\alpha_i^{k^*} < 0$ , then set  $s_i = -\alpha_i^{k^*}$  and  $u_i = 1$  and  
if  $i \le m^*$  and  $\alpha_i^{k^*} \ge 0$ , then set  $t_i = \alpha_i^{k^*}$  and  $\ell_i = 1$ .

Set all other variables to zero.

## **7 Examples**

In this section we illustrate the benefits of weighting using the proposed algorithm. We first determine the breakdown points for 21 one- and two-predictor designs that cover a wide range of possible patterns, all of which are based on  $n = 500$  observations. In the one predictor case, we generate n observations from either a uniform, exponential (with mean 1) or normal distribution, as these represent varying degrees of nonuniformity in the design. We also consider the situation where a certain percentage (either 10% or 20%) of the observations are replaced by observations placed at roughly four standard deviations away from the mean of the predictor. The existence of unusual values for the predictors (called leverage points in the statistics literature) is of particular interest, since it is well-known that LAD regression is very sensitive to leverage points.

We also examine two-predictor (multiple) regressions by generating two predictors using the six possible combinations of uniform, exponential, and normal distributions. We also examine the effects of leverage points, by replacing 20% of the observations with values placed at roughly four standard deviations away from the mean of the predictor for both predictors.

The results are given in Table 1. For each design the breakdown point (expressed as a percentage of the total sample size) is given for LAD, weighted LAD based on applying the algorithm for choosing weights once, and weighted LAD based on applying the algorithm for choosing weights iteratively. Iterating is done by treating the weighted design **WX** (where **W** is a diagonal matrix of weights) as the current design, and reapplying the algorithm. At each iteration, the breakdown point is determined, and iteration continues until the breakdown point stops increasing (the total number of iterations in each case is given in parentheses in the table). These breakdown points were computed exactly here, but in the situation where a user is faced with designs too large to determine the breakdown exactly, we suggest utilizing the heuristic for finding a good upper bound of the breakdown suggested by Giloni and Padberg ([4]) and then iterating until the upper bound no longer increases (of course, another possibility would be to just iterate once).

The table makes clear the benefits of weighting. Just one iteration of the weighting algorithm typically increases the breakdown point 3-5 percentage points, and as much as 6-7 percentage points when there are leverage points. Even more impressively, iterating the weighting algorithm leads to gains in breakdown of at least 5 percentage points in most cases, and as much as 10-15 percentage points in many. The weighted LAD estimator is much more robust than the LAD estimator, and therefore more trustworthy as a routine regression tool.

We conclude with discussion of a well-known data set from the robust regression literature, the so-called Stars data set  $(12)$ , p. 27). Figure 1 contains three graphs. At the top left is a scatter plot of the original data, which is a plot of the logarithm of the light intensity versus the logarithm of the temperature at the surface of 47 stars in the star cluster CYG OB1. The plot (called a *Hertzsprung-Russell star chart*) also includes the least squares regression line, the LAD regression line, and the weighted LAD regression line using the weights defined by our weight selection algorithm, including iteration. There are four obvious outliers in this data set all with logged temperature approximately equal to 3.5. These outlying data points are what are referred to as "red giants," as opposed to the rest of the stars which are considered to lie in the "main sequence." It is apparent that the least

Design	Leverage	LAD breakdown	WLAD breakdown	WLAD breakdown
		point	point (1 iteration)	point ( $\#$ iterations)
Exponential		14.0%	17.8%	$26.6\%$ (4)

Uniform/Uniform	20%	11.0%	13.2%	$20.6\%$ (3)

Table 1: Breakdown points for various designs.

squares line is drawn towards the red giants, which is not surprising, given its breakdown point of  $1/47$ . By contrast, the weighted LAD line is unaffected by the outliers, and goes through the main sequence. The WLAD line has breakdown 10/47 if only one iteration of the weighting algorithm is used, and increases to 13/47 with two iterations.

It is interesting to note, however, that the LAD line is also drawn towards the outliers, despite the fact that the LAD line has not broken down (its breakdown point is 5/47, so the four outliers are not enough to break it down). This illustrates that weighting can be helpful if outliers occur at leverage points, even if the LAD estimator has not broken down. The top right plot reinforces that LAD has not broken down. In this plot the light intensities of the four giants have been further contaminated (by adding 10 to the values). The least squares line follows the outliers, but the LAD line is virtually identical to what it was in the original plot, since it has not broken down (although it still does not follow the main sequence, as the weighted LAD line still does). In the third plot of the figure, two more stars have their light intensities contaminated. Since there are now 6 outliers, the LAD line breaks down, and is as poor as the least squares line, while the weighted LAD line is still resistant to the outliers.

#### **8 Conclusions and Directions for Future Research**

In this paper, we have demonstrated that weighted LAD regression is a regression technique whose robustness properties can be studied by mathematical programming methods. We have developed a computationally feasible method for calculating the optimum weights and have demonstrated that the optimum breakdown can be significantly increased by a judicious choice of weights. These results leave open the statistical properties of weighted LAD regression, which would be fruitful topics for further research. These include study of the asymptotic properties of weighted LAD regression, its small-sample properties, and investigation of whether nonlinear weights might lead to better performance.
