Excessive(?) Entry of National Telecom Networks, 1990-2001

Christiaan Hogendorn*

July 12, 2004

Abstract

We document entry and capacity expansion in US long-distance fiber-optic networks before and during the “telecom boom.” We disentangle the many swaps and leases between networks in order to measure owned route miles versus route miles shared with other carriers. Entry appears much more moderate when these shared miles are not counted. Preemption strategies can lead to excessive entry, and we find evidence for preemptive behavior regarding total miles (including swaps and leases) but less for preemption regarding owned miles. We conclude that entry was excessive only with regard to swaps and leases, but not with regard to the physical building of the networks.

JEL classification: L11, L13, L96

Keywords: telecommunications, investment, preemption

1 Introduction

During the late 1990s there was tremendous capacity expansion and entry of new firms in the North American long-haul telecommunications industry. These expansions were driven by very fast demand growth for Internet and other data-oriented telecom services and by exponential decreases in the cost per bit transmitted using fiber optic communications equipment. But by 2001, competition and slowing demand growth were squeezing the profits of these carriers, and an equally unprecedented slowdown in spending occurred. The problems in the telecommunications sector have been blamed for dragging down growth in the entire U.S. economy.

As the expansion turned to bust, discussion of “excessive entry” and a “fiber glut” became increasingly common. Generally the fiber glut story revolves around three premises. First, Internet growth was not as fast as expected, and in particular, not as fast as Worldcom claimed (Odlyzko 2003). Second, the still-high growth rate of data traffic was “...not nearly fast enough to use all of the millions of miles of fiber-optic lines that were buried beneath streets and oceans in the late-1990s frenzy.”¹ Third, the

¹Yochi Dreazen, “Behind the Fiber Glut – Telecom Carriers Were Driven By Wildly Optimistic Data on Internet’s Growth Rate,” *The Wall Street Journal*, September 26, 2002, pg. B1.

equipment used to send data over fiber optic cable improved dramatically so that each strand of fiber could carry many more gigabits of data: “Perhaps never before has the efficiency of an industry’s technology gotten so far ahead of demand.”²

These gloomy statements have become the conventional wisdom: there was excessive entry of fiber optic networks based on overoptimism and strategic behavior. In this paper, we analyze whether this conventional wisdom is correct based on new data on sunk investments (actual miles of right-of-way) and non-sunk investments (relatively fungible swaps and leases of conduit space and fiber). We also run empirical tests for preemptive behavior that might lead to *ex post* unprofitable networks. We find that more than half of the entry was non-sunk investment, and evidence for preemption is largely limited to these non-sunk investments. We conclude that the “excessive” label is applicable only to these swaps and leases.

To our knowledge there is no economics literature analyzing this industry’s growth and decline. Indeed, very little data has been collected on which firms entered when and where. Until 1998, Jonathan Kraushaar of the Federal Communications Commission published a yearly update on long

²Dennis Berman, “Behind the Fiber Glut – Innovation Outpaced the Marketplace,” *The Wall Street Journal*, September 26, 2002, pg. B1.

distance fiber optic networks, but this was discontinued just as industry investment took off. In this paper we present newly collected data that merges Kraushaar's work with publicly available information on firms' entry decisions up to the end of 2001.

Section 2 discusses the relevant theory of firm entry, investment, and sunk costs and applies it to the national telecom network industry. We also compare today's telecoms crisis to the problems of late nineteenth century railroads. In section 3, we describe our data sources and methods of data collection. We analyze the pattern of entry and the decrease in industry concentration in section 4. In section 5, we test for preemptive behavior. Section 6 concludes.

2 Sunk Costs and National Fiber-Optic Networks

The building of the national fiber optic networks is another chapter in the peculiar history of U.S. infrastructure industries. This history started with the canal boom of the early nineteenth century, reached its most dramatic episode in the railroad booms and busts of the late nineteenth century, and has continued since then with electricity transmission, Interstate highways, and cable television among others. All of these industries have been politically as well as economically important, and all have been characterized by

financial instability and/or heavy government regulation.

In particular, the recent telecom boom and bust has been compared to the nineteenth century railroad experience, and the two do appear similar in many regards. In both cases, a large number of firms gained access to rights-of-way between major cities, built multiple parallel routes, and then engaged in intense competition that left many of them bankrupt. But we discuss below that the key to this comparison is the nature of sunk costs in the two industries, and that in fact the two are quite different in this regard.

Entry decisions in high-sunk-cost industries can be represented using a two-stage game (Sutton 1998). In stage 1, firms make irreversible investments that determine their characteristics, such as product variety or quality or some measure of capacity. These investments are industry-specific sunk costs, so the firms do not exit the market later in the game. In stage 2, the firms compete according to Cournot, differentiated Bertrand, or some other type of competition. The terms of this competition are affected by the stage 1 decisions. Sutton suggests that a very loose requirement for a solution to this game is a criterion of viability. That is, firms will not make stage 1 investments that they cannot recoup as operating profit in stage 2.

Faulhaber and Hogendorn (2000) argue that for infrastructure industries like telecom networks, the basic game structure can be further refined as

follows: In stage 1, firms invest in *distribution capacity* that determines where they can offer service in geographical space. Then stage 2 can be divided into two parts. In stage 2a, firms invest in *production capacity* that determines how much they can produce in each area that they serve, and in stage 2b they compete in each area subject to these production capacity constraints. The key to this interpretation is that distribution capacity is a sunk cost because investments like rights-of-way, conduits, and utility poles have no alternative use and are not fungible. But production capacity is not sunk because investments like locomotives, telephone switches, and transformers can be resold or redeployed and are therefore fungible.

Under this interpretation, the key to competition between infrastructure firms is geography, since the sunk distribution capacity means that once a firm enters a territory it can commit not to leave. Production capacity, on the other hand, may affect short-run competitive outcomes (for example, it might lead to Cournot outcomes in the manner of Kreps and Scheinkman (1983)), but it does not carry long-run commitment value. For example, entry by a second railroad between two cities would irrevocably increase the number of competitors to two, but it would not inevitably lead to zero-profit Bertrand competition since production capacity (e.g. the number of locomotives) could be adjusted periodically.

For long-haul fiber optic networks, distribution capacity involves securing a right of way, burying protective conduits in this right-of-way, building “huts” to house equipment at intervals along the route, and placing fiber-optic cable inside the conduit. Each strand of fiber has very large data capacity, each cable contains many strands of fiber, and many firms own multiple conduits, so for the foreseeable future no further upgrades to this distribution capacity are necessary.³

It is prohibitively expensive to acquire new rights-of-way, so the networks generally follow highways, railroads, and natural gas pipelines. In fact, several of the major networks are associated with companies that own these rights-of-way. Williams, for example, is a natural gas pipeline owner, while Qwest was originally a division of the Southern Pacific Railroad. There is some irony in the comparison with nineteenth century railroads because in many cases the same rights of way were used during the fiber boom.

Production capacity consists of terminal equipment that takes electronic data from many sources, switches and combines it into channels, and converts it to optical signals using lasers. This is called “lighting” the fiber in the industry jargon. Such equipment is expensive but can be moved, resold,

³There are periodically advances in the quality of fiber-optic strands, so systems in which it is easier to install new fiber have an advantage in the long run.

expanded, and contracted given sufficient lead time. There are some sunk costs involved, so the quantity of lit fiber has some short-run commitment value. But in the long run, overcapacity and low prices on a particular route should lead to redeployment of equipment away from that route. For now the marginal cost of production capacity relative to the size of demand is very small and appears to be causing very low prices.

Why did numerous firms invest in sunk distribution capacity when there were signs that operating profits would be low? Part of the answer is that the number of firms that installed production capacity is much larger than the number that installed distribution capacity. The reason this was possible is that owners of rights-of-way were willing to sell indefeasible rights of use (IRUs) by means of which firms could obtain either space in conduits or dark fiber (fiber optic cable with no terminal equipment attached at the ends). These IRUs convey many of the rights of ownership, but they are typically limited to 20 years, can be dissolved by mutual agreement, and are frequently abrogated by bankruptcy courts. Furthermore, despite the careful language of IRU agreements, in an industry with rapidly changing technology there are likely to be many noncontractables that could render an IRU economically obsolete earlier than its legal expiration.

The fact that so many fiber-optic networks are based on IRUs means

that sunk distribution capacity is much less than the number of national networks would suggest. Firms that go bankrupt and hold IRUs are likely to exit the industry once and for all. Only those firms that actually hold right of way are committed to continuing employment of their assets even in the face of bankruptcy reorganization.

Contrast this situation to the nineteenth century railroad boom. Arthur Hadley (1885) discussed how the sunk-cost nature of railroad right of way created perpetual instability in the railroad industry. When competition on a route (New York to Chicago was particularly competitive) was too great to support all the lines on the route, some railroads went bankrupt. But their sunk investment in right of way had no alternative use, so the insolvent line simply emerged from bankruptcy with its debt reduced, and the number of competitors remained the same. This pattern, and the companies' collusive attempts to combat it, eventually led to regulation of the industry.

3 Data

Our data measure the distribution capacity actually installed and the amount installed under IRUs and similar agreements. The simplest summary mea-

sure of distribution capacity is total route-miles of network.⁴ Since all networks in the sample reach all major American cities, higher route miles indicate more small cities served and/or more redundancy in the network. In nearly all cases, the promotional and technical materials made available by telecom firms do not differentiate between route miles owned outright and those owned through IRUs. Thus we reconstruct the process by which each network was built, noting which routes are based on IRUs (*shared miles*) and which on owned right of way (*owned miles*). In some cases, routes are jointly owned, in which case we count one-half the miles for each of two owners and one-third for each of three. Jointly owned routes are a much smaller portion of total mileage than are IRUs and do not greatly affect the totals.

During the period 1986-1998, the FCC collected similar data from the inter-exchange (long distance) telephone companies. These data were compiled and analyzed by Jonathan Kraushaar in what was then the Commission's Common Carrier Bureau, and the reports continue to be available at the FCC's website. The FCC data collection proceeded through voluntary questionnaires and telephone calls, and they received a high response

⁴Each route mile typically contains many strands of fiber-optic cable, so measures of "fiber miles" or "strand miles" are usually many times larger than route miles.

rate. Toward the end of the sample period, they expressed concern that fiber routes miles were being double-counted, precisely for the reasons we discussed above. We use the FCC data for nearly all firms that had fiber networks during the period 1990-96, with some corrections for shared mileage. For 1997-98, we use the FCC data primarily as a check against our own data. From 1999-2001 we must rely on our own data exclusively. We found that in most cases our data was consistent with the FCC's.

Our main source for total route miles is the firms' annual reports and investment prospectuses as filed with the Securities and Exchange Commission and available through the online EDGAR database (primarily forms 10-K and S-4). Some companies included very meticulous network data with these filings, while others simply mentioned route miles in passing.

To supplement that source, we also searched each company's press releases using the archives on LEXIS/NEXIS. In many cases, firms obtained IRUs by swapping access to their own right of way for access to the right of way of their competitors. The firms often announced and promoted these swaps as an inexpensive way to build their network quickly. In several cases, firms swapped access to a preexisting IRU for a preexisting IRU on another firm's route, so that the swaps could be more than one layer deep. Because of this, we frequently know that a route is based on an IRU but cannot

definitely determine the source of that IRU. Fortunately, this problem does not affect the computation of owned versus shared route miles.

The firms' reports were checked on a route-by-route basis against network maps available at the companies' web sites (in most cases) or from Internet service provider resellers (for Qwest, MCIWorldcom, McLeodUSA, and ENRON). They were also checked against the map "North American National and Regional Fiberoptic Long-Haul Routes Planned and In Place" published by KMI Research and dated May 2002. The inconsistencies were minor.

Although we are quite confident that the routes identified as shared are in fact shared, there are probably additional IRUs and swaps that were not reported. As such, the database is conservative since it attributes all other miles as owned. We were not able to find as complete data on Sprint as on other networks. All our sources suggest that Sprint's network was largely completed before the sample period and not significantly expanded thereafter. For years in which no data was available for Sprint, we have assumed no expansion and entered the previous year's figure.

The sample is limited to firms that either achieved national reach or had announced aspirations to national reach. Regional networks (which include the local telephone companies) are not counted. They actually include the

majority of fiber in the United States, but they do not compete in the same national market. Providing national coverage by piecing together circuits from regional networks is too expensive and unreliable to be competitive.⁵ We also exclude firms that purchased access to national networks but did not own any mileage of their own and did not participate in any swaps of IRUs; these were customers, not peers, of the carriers listed.

4 Entry and Investment

We now document the pattern of entry and show that a large proportion of investment is shared miles. When only owned miles are considered, entry appears more moderate and industry concentration more typical of a high-sunk-cost industry.

⁵The excluded regional networks are the Regional Bell Operating Companies (RBOCs) and Alltel, Black Hills Fibercom, C3 Networks, Columbia Transcom, Connectiv, Dominion Telecom, Dukenet, El Paso Global Networks, Electric Lightwave, Entergy, Florida Fiber Network, FPL Fibernet, GPU Telecom, Iowa Network Services, ITC Deltacom, Kentucky Data Link, Logix Communications, MP Telecom, NEON, Norlight, Onvoy, Palmetonet, Progress Telecom, SON Communications, Telergy, Time Warner Telecom, and Valleytel. Several of the firms that are included are essentially regional carriers that expanded to national reach through IRUs. These are DTI, EPIK, Metromedia, Pathnet, and Touch America.

Table 1 shows total network route miles (owned plus shared) by firm for the period 1990-2001. We include both “lit” and “dark” miles since the dark miles would still be expected to exert competitive pressures in the long run. During the early 1990s, three large long distance companies, AT&T, MCI, and Sprint, had been joined by Williams, a natural gas pipeline company that built a nationwide fiber optic network. Williams sold this network to Worldcom in 1995.⁶

In 1997 – two years after the Netscape initial public offering launched the Internet as a major commercial force and one year after passage of the Telecommunications Act – growth in route miles increased rapidly. This was a combination of expansion by existing networks and *de novo* entry. By 2001, there were 19 national networks, but profits were low and Pathnet had exited the market, while EPIK contracted back to its Florida base. In 2002, almost all of these firms were in bankruptcy.

EPIK’s sudden contraction from national to regional network demonstrates that the distribution capacity of some of these companies did not consist of sunk assets. Tables 2 and 3 show route miles actually owned by each firm in each of the years and the percentage of total route miles that

⁶The FCC’s Worldcom data appears to include regional networks. We use only national route miles reported by Worldcom (and its predecessor LDDS) in SEC filings.

were owned.

At the beginning of the 1990s, all networks were owned outright by the carriers. But entry in the later 90s involved so many swaps and IRUs that many “national” carriers owned only a small percent of their rights of way, and in a few cases owned none at all. The IRU strategy does not appear to have been a temporary expedient to expand network reach, since most carriers were decreasing their percentage owned even as they served more route miles.

The bulk of total investment in network route miles came during 1998, 1999, and 2000. The majority of the new miles in this period were shared. New right of way built in this period is mostly accounted for by upgrades to the old AT&T and MCIWorldcom networks and the entry of three new major networks, Qwest, Level 3, and Williams (see Figure 1). One way to interpret this is that four incumbents were joined by three entrants and fringe firms that were partially dependent on the seven major networks.

These data suggest that the industry did not experience overbuilding and ruinous competition along the same lines as the railroads of the late 1800s. Rather, actual construction of new rights of way represented modest entry, but the swaps of IRUs created a very competitive environment in which prices fell.

The Herfindahl-Hirschman Indices (HHIs) and the equivalent number of equal-sized firms (calculated from the inverse of the HHI) for each year based on total miles and owned miles appear in Table 4. Not all of the networks use their capacity equally, but these measures based on route miles do provide a guide to the potential long-run industry structure.

The difference between competition in terms of total miles and owned miles is striking. Using total miles, the industry has moved from an oligopolistic HHI to a very competitive one. But using owned miles, the industry remains above the 1,000 limit for government scrutiny of mergers based on the Department of Justice's *1992 Horizontal Merger Guidelines*. Still, there were eight equivalent equal-sized firms using owned miles, which is a large number of competitors by the standards of previous infrastructure developments such as railroads and early telephone.

We have now shown that shared miles made up a very substantial portion of entry into the industry. Total miles grew so fast as to push concentration measures into an unsupportable region. But using owned miles, entry was more measured and concentration remained in the oligopoly range. By these measures, we conclude that while total miles may not have been viable, owned miles were probably much closer to viability (if they had not been shared out). Why would firms invest in miles that were not viable?

One answer is that there was a race to capture a leading position in the industry, and the investment was preemptive. In the next section, we test this hypothesis.

5 Testing for Preemption

Some of the expansion in route miles was presumably due to the growth of the Internet and the liberalization of the local access market under the Telecommunications Act of 1996. This still leaves open the question of whether additional, “excessive” investment was part of preemptive behavior.

Gilbert and Lieberman (1987) (hereafter GL) develop an econometric model to test for preemption, i.e. entry or growth deterrence and a race to appropriate a profitable opportunity. GL collect data on 24 chemical products produced by 3 to 20 firms, circa 1960 through 1982. The independent variable is binary: $y_{i,j,t} = 1$ if firm i increased its capacity to produce product j in year t by more than 5%. The 5% threshold is arbitrary, but they claim that using other thresholds does not affect the results. The reason to use a binary variable is to avoid scaling problems since small firms have huge percent changes in their early years. All observations begin two years after the firm enters the industry, so the startup capacity investment is excluded.

GL’s independent variables are constructed from firm i ’s production ca-

capacity and the total industry output. They are: capacity utilization (averaged over two years), growth rate of output (averaged over four years), the firm's share of total capacity, the change in the firm's capacity share (over a two year period), and a "bandwagon effect" that measures the percent increase in all rivals' capacity. Because they expect that large and small firms may behave differently, they interact all the variables with the firm's capacity share.

They argue that the coefficients on these variables provide a test for preemption. If the market model is one of preemption, then investment will not be affected by capacity share since other, strategic considerations will drive firm behavior. A negative response to bandwagon investment indicates successful preemption by other firms. Also, preemption requires that investment respond positively to capacity utilization because preemption implies an effort to keep capacity low relative to revenue.

Suppose that instead of preemption, the market is growing in a symmetric fashion. The probability of a firm investing aggressively may not be affected by capacity utilization, but it responds negatively to changes in capacity share since firms will roughly maintain their market shares. Investment should respond positively to bandwagon investment by others since firms have to keep up with one another in order to maintain their positions

in the industry.

GL's estimates show small firms, below 9% market share, using preemptive strategies while large firms seem to maintain market share. To bolster this result, they estimate a restricted model with only the variables expected to affect preemption. The preemption model is rejected on the basis of a likelihood ratio test in favor of the full model. Its estimates again suggest that large firms can be preempted.

We apply this model to our data on the fiber optic industry. The company reports frequently give plans to put new route miles in service within one year, so we convert all lags to one year. We face three main difficulties in translating GL's model, namely what constitutes capacity, output, and capacity utilization.

For a measure of capacity we use route miles. As we have argued above, all of the networks are similar in terms of coverage of the entire country, so additional route miles imply a more dense, more robust network. The actual production capacity of each link in the network is not important because the advances in fiber optic technology essentially eliminated data throughput constraints. Thus mileage, and the associated density of the network, is the key capacity decision. We label firm i 's total and owned miles in year t by $M_{i,t}^T$ and $M_{i,t}^O$ respectively.

We cannot directly observe the output of these communications networks; such data are difficult to measure even for the owners of the networks themselves and are not publicly available. Instead we proxy for industry output with industry revenue. Revenues of the long distance networks themselves are the seemingly logical focus of interest, but there are two problems with using them. First, many of the firms, such as AT&T, derive most of their revenue from lines of business not directly related to their long-haul networks. The firms do not report sufficiently disaggregated revenue to correct for this problem. Second, the networks' revenue is determined endogenously with investment in route miles, so proper estimation would require good instruments. As an alternative, we use total revenue of the U.S. telecoms industry. Since these data include various local telephone, wireless telephone, and business services, they should remove much of the endogeneity problem and provide an index for opportunities to build additional route miles. The source for these data is the International Telecommunications Union *Yearbook of Statistics*, 2003 and 2000 editions. Yearly revenue (REV_t) and growth in revenue ($GROW_t = (REV_t/REV_{t-1}) - 1$) are reported in Table 5.⁷ Revenue is measured in 1995 dollars using the consumer price index.

⁷An alternative growth measure, Internet traffic growth, proved to be highly collinear.

Finally, we need a measure of capacity utilization. The same problems with output data occur here too, so we compare growth in revenue to growth in capacity. We calculate a Revenue per Mile Index for both total and owned miles, RMI_t^T and RMI_t^O , by comparing revenue per mile in year t with revenue per mile in 1990. Thus, if firm i 's total and owned miles in year t are $M_{i,t}^T$ and $M_{i,t}^O$,

$$RMI_t^j = \frac{\frac{REV_t}{\sum_i M_{i,t}^j}}{\frac{REV_{1990}}{\sum_i M_{i,1990}^j}} \quad j = T, O$$

In 1990 there appear to have been modest opportunities to expand route miles since there was a gradual increase in miles in the succeeding years. Relative to this base level, $RMI > 1$ indicates relatively better opportunities while $RMI < 1$ indicates relatively poorer ones.

An interesting feature of these data is that in 1995-97, there were arguably opportunities to add route mileage (based on revenue), particularly when looking at owned miles only. By the end of the sample period, revenue per mile has fallen sharply. Owned miles show much less of this trend than total miles due to the extensive use of shared mileage.

Given these interpretations of capacity, output, and capacity utilization, we can construct the rest of GL's independent variables as follows. Firm i 's

share of total industry mileage in year t is

$$SHARE_{i,t}^j = \frac{M_{i,t}^j}{\sum_i M_{i,t}^j} \quad j = T, O$$

The change in that share from year $t - 1$ to year t is

$$DELSHARE_{i,t}^j = \frac{SHARE_{i,t}^j}{SHARE_{i,t-1}^j} \quad j = T, O$$

The “bandwagon effect” that measures investment by firm i ’s competitors during year t is

$$BAND_{i,t}^j = \frac{\sum_{k \neq i} (M_{k,t}^j - M_{k,t-1}^j)}{\sum_{k \neq i} M_{k,t-1}^j}$$

Note that the bandwagon variable is different from $DELSHARE$ because it concerns investment in the current year and it does not account for a firm’s own investment. The correlation between $BAND$ and $DELSHARE$ is $R = 0.10$ for total miles and $R = 0.14$ for owned miles.

Because small firms may differ from large firms, all variables are interacted with $SHARE$. Since investment decisions must be taken prior to their realizations, all variables are lagged one year except for $BAND$.

The dependent variable is binary and measures whether route miles were increased substantially in a given year. For some threshold change d , define

$$Y_{i,t}^j = 1 \quad \text{if} \quad \frac{M_{i,t}^j - M_{i,t-1}^j}{M_{i,t-1}^j} > d$$

and 0 otherwise. The reason to use the binary variable is that smaller firms have huge percentage additions in some years, which introduces scaling

problems. We want to choose d to represent firms that made significant investments over and above the general trend in the industry. We remove the first year for new entrants from the sample. Then we observe the median and 40th, 60th, and 70th percentile growth in route miles across all observations (see Table 6). We run several regressions, defining the dependent variable using d equal to each of these percentile values.

The results of probit analysis using total miles are reported in Table 7. The different cutoff levels d seem to affect significance levels more than magnitudes of the estimates. Changes in market share clearly do not affect investment, which is characteristic of a preemptive environment. The bandwagon effect is positive for small firms but negative for larger ones (though only significant for the median case). This suggests that small firms may have been preempting large ones. For the median case ($d = 7.3\%$), the boundary between “large” and “small” firms is 10.8% market share, roughly the size of the four major incumbents.

Following GL, we also ran regressions omitting the variables *SHARE* and *DELSHARE* since they are not expected to matter under preemption. The signs of the estimates do not change on the remaining variables. Likelihood ratio tests accept the preemption model for the 40th, 50th, and 60th

percentile cases, and reject for the 70th percentile case.⁸ This suggests that preemptive behavior, at least by small firms, is a plausible explanation for investment in total miles.

Table 8 reports results using owned miles only. The sample is slightly smaller because in four cases firms entered the market with zero owned miles in their first year. In many respects, the results are similar to total miles. Again the coefficients on *BAND* suggest that larger firms may have been preempted by smaller ones, with the boundary between firm sizes at about 13%. However, the *DELSHARE* variables are now significant also, which is not expected in GL's discussion of preemption.

The restricted preemption model fits more poorly for owned miles than for total miles. For all but the 70th percentile case, it is rejected by likelihood ratio test.⁹ No doubt this is because of the greater importance of the *DELSHARE* variables. Thus, the evidence for preemption is much more limited and more mixed than in the total miles case. We interpret this to mean that investment behavior with regard to owned miles is less well explained by the GL model and probably reflects a variety of strategies by different firms.

⁸p-values of 46%, 81%, 37% and 4% respectively.

⁹p-values of 0.3%, 0.6%, 1.1%, and 25.9% respectively.

6 Conclusion

We have examined the number of fiber-optic route miles built by U.S. telecom firms from 1990-2001. By sorting through each firm's SEC reports and press releases, we have been able to discover which routes are based on sunk investments in right of way and conduit and which are based on relatively non-sunk investment in IRUs. We find that more than half of total route miles added during this period were based on non-sunk forms of investment. We conclude that the loss-producing level of competition that has prevailed since 2001 is due more to the willingness of firms to sell IRUs than to actual over-investment like that which occurred in the nineteenth century railroad boom.

We calculated a Revenue per Mile Index based on industry-wide changes in revenue per route mile from a 1990 base. This measure suggests that there were opportunities for increased investment in route miles in the mid 1990s, but that investment after that proceeded much faster than revenue growth. Using Gilbert and Lieberman's (1987) model of oligopoly investment, we find some evidence for preemptive behavior regarding total miles, which could lead to excessive entry from an *ex post* perspective. Applying the same analysis to owned miles produces less evidence of preemption. Large firms may have been deterred from adding owned route miles due to the entry

of smaller firms, but firms also seem to have been responding to changes in market share.

Our general conclusion is that the only “excessive” element of national fiber optic network investment was the very extensive sharing of route miles between firms. Some of this sharing may have involved preemptive behavior, and it led to remarkably low concentration for an industry with such high fixed, sunk costs. Not including this sharing, the underlying investment in owned route miles was more moderate, led to fairly reasonable concentration, and does not appear to have been preemptive.
